Abstract: NiFe (oxy)hydroxides nanosheets were synthesized on nickel foams via co-precipitation and electrochemical activation. It is found that the phosphate precursors (Na_3PO_4, Na_2HPO_4 and NaH_2PO_4) have diverse effects on the morphology and thus the oxygen evolution reaction activity of the formed final catalysts. The resulting NiFe (oxy)hydroxides nanosheets prepared with Na_2HPO_4 demonstrate a low overpotential of 205 mV to achieve a current density of 50 mA/cm^2 with a Tafel slope down to 30 mV/dec in 1 mol/L KOH, and remain stable for 20 h during stability test.
Key words: NiFe (oxy)hydroxides; Fe-based phosphate; oxygen evolution reaction; electrochemical activation

1 Introduction

Electrochemical water splitting provides a sustainable and pollution-free method for mass production of high-purity hydrogen fuel [1−4]. In contrast to the rather straightforward hydrogen evolution reaction (HER) with a relatively low overpotential, the oxygen evolution reaction (OER) involves a complex four-electron transfer process with a large overpotential, which limits the overall efficiency of water electrolysis [5,6]. Noble metal compounds such as RuO_2 and IrO_2 have been used as commercial OER catalysts, while the scarcity and high cost of noble metal compounds hinder the

industrial applications [7−9]. Accordingly, research efforts are increasingly devoted to the design and fabrication of energy-efficient noble-metal-free catalysts, e.g., transition metal-based oxides [10,11], phosphides [12], (oxy)hydroxide [12,13], and phosphates [14].

Among them, transition metal (oxy)hydroxides have been reported to be promising candidates for OER electrocatalysts due to the low-cost, earth abundant, environmentally benign, unique atomic geometry structure, and high catalytic behavior [15−20], in particular for Ni/Fe-based catalysts [14], although the real active site of Ni/Fe-based catalysts is still in debate [21]. For example, FRIEBEL et al [22] found that Fe^{3+} cations in

γ-Ni$_{1-x}$Fe$_x$OOH exhibit a lower overpotential than Ni^{3+} cations in either γ-Ni$_{1-x}$Fe$_x$OOH or γ-NiOOH, which means that Fe^{3+} is the active site. However, LI et al [23] proposed that the doping of Fe^{3+} promoted the formation of Ni^{4+}, which in turn directly correlated to the enhanced OER performance. Despite of these, there is no doubt that the strong synergistic effect between Ni and Fe will contribute to the enhanced OER activity. In addition, it is noted that the metal phosphates can be converted to the metal (oxy)hydroxide through anion exchange in alkaline conditions [24], and many studies have demonstrated that the morphology and structure of metal phosphates can be varied with the change of phosphate precursors [25]. Therefore, the phosphate precursors (e.g., Na$_3$PO$_4$, Na$_2$HPO$_4$ and NaH$_2$PO$_4$) may also have profound effects on the morphology and structure of the metal (oxy)hydroxides and thus their OER activity; however, they remain rather unexplored.

To address these challenges, we prepared Fe-based phosphate precatalysts on Ni foams (NF) using various phosphate precursors (Na$_3$PO$_4$, Na$_2$HPO$_4$ and NaH$_2$PO$_4$) via a facile co-precipitation approach and evaluated their OER performance in alkaline conditions. Our structural analysis indicates that the iron phosphates-based precatalysts will spontaneously convert into nickel−iron (oxy)hydroxides (NiFeO$_x$H$_y$) as the final catalysts under electrochemical activation process (cyclic voltammetry (CV) scans) in alkaline conditions, which exhibits different morphologies with the change of phosphate precursors. To be specific, the final catalysts synthesized with Na$_2$HPO$_4$ prefer to form two-dimensional nanosheets, while these with Na$_3$PO$_4$ and NaH$_2$PO$_4$ mainly consist of aggregated nanoparticles with some dispersed nanosheets. The resulting NiFeO$_x$H$_y$ nanosheets synthesized with Na$_2$HPO$_4$ possess a flower-like morphology with rich active sites, allowing facial contact of solution, fast release of the produced gaseous molecules, and effective electron transfer, which thus provides more active sites and high efficiency for the reaction with a remarkably high and durable OER activity.

2 Experimental

2.1 Chemicals

Potassium hydroxide (95% KOH, Aladdin),

ethanol absolute (CH$_3$CH$_2$OH, Sinopharm), iron nitrate nonahydrate (Fe(NO$_3$)$_3$·9H$_2$O, Aladdin), sodium phosphate, tribasic, anhydrous (Na$_3$PO$_4$, Aladdin), disodium hydrogen phosphate dodecahydrate (Na$_2$HPO$_4$·12H$_2$O, Sinopharm), sodium dihydrogen phosphate dihydrate (NaH$_2$PO$_4$·2H$_2$O, Sinopharm), Ni foam (NF, 99.9% Ni, thickness 1.5 mm, Kunshan Metal Material Tech, Suzhou, China), carbon cloth (W0S1011, thickness 0.36 mm, CeTech Co., Ltd), and highly purified water (> 18 MΩ·cm resistivity) were used. Before using, Ni foams were sonicated in 1 mol/L HCl for 0.5 h and washed in purified water.

2.2 Synthesis of NiFeO$_x$H$_y$/NF

NiFeO$_x$H$_y$/NF was synthesized through a facile co-precipitation and electrochemical activation strategy. Firstly, 0.025 mmol Fe(NO$_3$)$_3$·9H$_2$O and 0.025 mmol Na$_2$HPO$_4$·12H$_2$O were dissolved in 100 μL water. Later, 50 μL alcohol was added and the mixture was sonicated for 0.5 h to get a light-yellow mixture. The precursors were dropped onto Ni foams (10 mm × 10 mm × 1.5 mm) and dried at room temperature for 1 h as the precatalysts, which were directly used as electrodes. Subsequently, NiFeO$_x$H$_y$ nanosheets will be constructed spontaneously on the NF during the CV activation process, which is named as NiFeO$_x$H$_y$/NF-1H. Similarly, NiFeO$_x$H$_y$/NF-0H and NiFeO$_x$H$_y$/NF-2H were synthesized via the substitution of Na$_2$HPO$_4$·12H$_2$O with Na$_3$PO$_4$ and NaH$_2$PO$_4$·2H$_2$O, respectively.

2.3 Characterization

Transmission electron microscopy (TEM) and high-resolution transmission electron microscope (HRTEM) were carried out by JEOL JEM 2100 microscope. The morphology and elemental composition of the synthesized catalysts were characterized by scanning electron microscopy (SEM, TESCAN MIRA3) equipped with energy-dispersive X-ray (EDS). X-ray diffraction (XRD) measurements were carried out on D/max 2550 VB equipped with Cu K$_\alpha$ radiation of 1.5418 Å. X-ray photoelectron spectroscopy (XPS) spectra were measured on Thermo ESCALAB 250XI system. Raman spectra were obtained on Horiba Scientific LabRAM HR Evolution with the excitation laser of 532 nm. The pH values were tested by PHS−25.

2.4 Electrochemical measurements

Electrochemical measurements were conducted using a CHI 760E electrochemical analyzer/ workstation (CH Instruments Inc. Austin) in 1 mol/L KOH (pH=13.8) at room temperature. A conventional three-electrode system was used, with Hg/HgO electrode as the reference electrode, a graphite rod (*d*6 mm) as the counter electrode, and the as-prepared catalysts as the working electrode. All samples were stabilized by 50 CV cycles before measurements. Linear sweep voltammetry (LSV) measurements were IR-compensated (90%) and measured at a scan rate of 5 mV/s. All the potentials were calibrated with respect to a reversible hydrogen electrode (RHE) via $\varphi(RHE)=$ $\varphi(Hg/HgO)+0.059pH+\varphi_0(Hg/HgO)$. The electro-chemical double layer capacitance (C_{dl}) was tested in 1 mol/L KOH solution with CV scanning from 1.04 to 1.14 V (vs RHE). Electrochemical impedance spectroscopy (EIS) measurements were carried out in the frequency range of 0.1 Hz to 100 kHz at an overpotential of 205 mV.

3 Results and discussion

The schematic illustration of the fabrication process is depicted in Fig. 1(a). The mixed solutions were prepared via dissolving Fe(NO$_3$)$_3$·9H$_2$O and the relative phosphate precursors (Na$_3$PO$_4$, Na$_2$HPO$_4$·12H$_2$O, or NaH$_2$PO$_4$·2H$_2$O) in water− alcohol solutions. The varying color of mixtures with different phosphate precursors was observed under visual inspection, suggesting the formation of iron phosphates. The obtained mixtures were then dropped on Ni foams as precatalysts and dried in

vacuum oven at 60 °C. The precatalysts were then directly used as the electrodes in alkaline electrolyte to form the metal (oxy)hydroxide as the final catalysts via electrochemical activation process. The conversion progress of the precatalysts of NiFeO$_x$H$_y$/NF-1H via electrochemical activation is demonstrated in Fig. 1(b). Generally, it can be stabilized after around 50 CV cycles with a scan rate of 50 mV/s, indicating the accomplishment of conversion of the precatalysts.

3.1 Crystal structure of pre- and final-catalysts

To verify the crystal structures of the pre-catalysts and final-catalysts, XRD analysis was carried out (Fig. 2). However, all the precatalysts with different phosphate precursors only show three pronounced sharp peaks at 44.5°, 51.8° and 76.4°, corresponding to the (110), (200) and (220) planes of the fcc nickel, respectively, while no clear diffraction patterns can be found for both metal phosphates and metal oxyhydroxides, which can be attributed to the amorphous nature of the metal phosphates and the low contents of both on the Ni foams [26].

The morphologies of pre- and final-catalysts of NiFeO$_x$H$_y$/NF-0H, NiFeO$_x$H$_y$/NF-1H, and NiFeO$_x$H$_y$/NF-2H are shown in Fig. 3. Surprisingly, although no obvious change can be found for NiFeO$_x$H$_y$/NF-0H (Figs. 3(a) and (d)) and NiFeO$_x$H$_y$/NF-2H (Figs. 3(c) and (f)) after the electrochemical activation (aggregated nanoparticles with a small amount of fragmentized nanosheets), NiFeO$_x$H$_y$/NF-1H (Figs. 3(b) and (e)) clearly shows a flower-like morphology with rich nanosheets, indicating that Na$_2$HPO$_4$ can engender

**Fig. 1** Illustration of fabrication process of NiFeO$_x$H$_y$/NF (a) and electrochemical activation process of precatalysts of NiFeO$_x$H$_y$/NF-1H via CV activation in alkaline condition (b)
Fig. 2 XRD patterns of pre-catalysts (a) and final-catalysts (b) of NiFeO$_x$H$_y$/NF-0H, NiFeO$_x$H$_y$/NF-1H and NiFeO$_x$H$_y$/NF-2H

Fig. 3 SEM (a, b, c) and TEM (d, e, f) images of final catalysts of NiFeO$_x$H$_y$/NF-0H (a, d), NiFeO$_x$H$_y$/NF-1H (b, e) and NiFeO$_x$H$_y$/NF-2H (c, f), HRTEM (g) and HADDF (h) images of NiFeO$_x$H$_y$/NF-1H, and corresponding elemental mapping images of Ni (i), Fe (j) and O (k)

the most appropriate state of the precatalysts for the formation of metal (oxy)hydroxide nanosheets. This is confirmed by a lattice fringe of 0.237 nm via HRTEM, corresponding to the (102) plane of NiOOH. In addition, we applied elemental mapping to analyze composition of the catalysts, which

suggests uniform distributions of Fe, Ni and O. It is interesting to note that Ni appears in the formed metal (oxy)hydroxide nanosheets, indicating slightly dissolving of Ni from the Ni foams during the electrochemical activation process. Moreover, EDS spectra demonstrate an abrupt drop of P content from 9.8% (precatalysts) to 0.3% (final catalysts) for NiFeO$_x$H$_y$/NF-1H, suggesting a quite complete conversion of metal phosphates to NiFe (oxy)hydroxides.

To further verify the surface chemical compositions and electronic structure of the obtained catalysts, XPS was conducted. The full XPS spectra of the final catalysts of NiFeO$_x$H$_y$/NF-0H, NiFeO$_x$H$_y$/NF-1H and NiFeO$_x$H$_y$/NF-2H indicate the existence of Ni, Fe and O in the catalysts (see Fig. 4(a)), where no P peaks can be found, in line with EDS results, further confirming the conversion of Fe phosphates to NiFe (oxy)hydroxides. Figures 4(b−d) show the high-resolution XPS spectra of O 2p, Ni 2p and Fe 2p, respectively. As shown in Fig. 4(b), the O 1s spectra show strong peaks at ~530.5 eV, corresponding to the O 1s in a hydroxide-like (M—OH) environment, i.e. NiFe (oxy)hydroxide [6,27−30]. The higher shoulder around 532 eV can be attributed to oxygen in the absorbed water molecules [31], while the lower shoulder around 528 eV is defined as the lattice oxygen in oxide environment (M—O) due to the formation of oxyhydroxides [30,32]. Ni 2p spectra in Fig. 4(c) exhibit binding energies (BEs) centered at ~854 and ~872 eV with two shakeup satellites at ~860 and ~878 eV, which can be attributed to Ni 2p$_{3/2}$ and Ni 2p$_{1/2}$ of Ni^{2+}, respectively [33,34], due to the surface oxidation of Ni in the air. More importantly, BEs centered at ~856 and ~874 eV can be assigned to Ni^{3+} in NiOOH [35]. XPS spectra of Fe 2p show main BEs at ~713 and ~727 eV, which can be assigned to Fe 2p$_{3/2}$ and Fe 2p$_{1/2}$ of FeOOH, respectively [36,37]. The BEs at ~711 and ~724 eV for Fe 2p$_{3/2}$ and Fe 2p$_{1/2}$ of Fe(OH)$_3$ suggest the exchanges of PO$_4^{3-}$ with OH$^-$, which leads to the further conversion during activation [38,39].

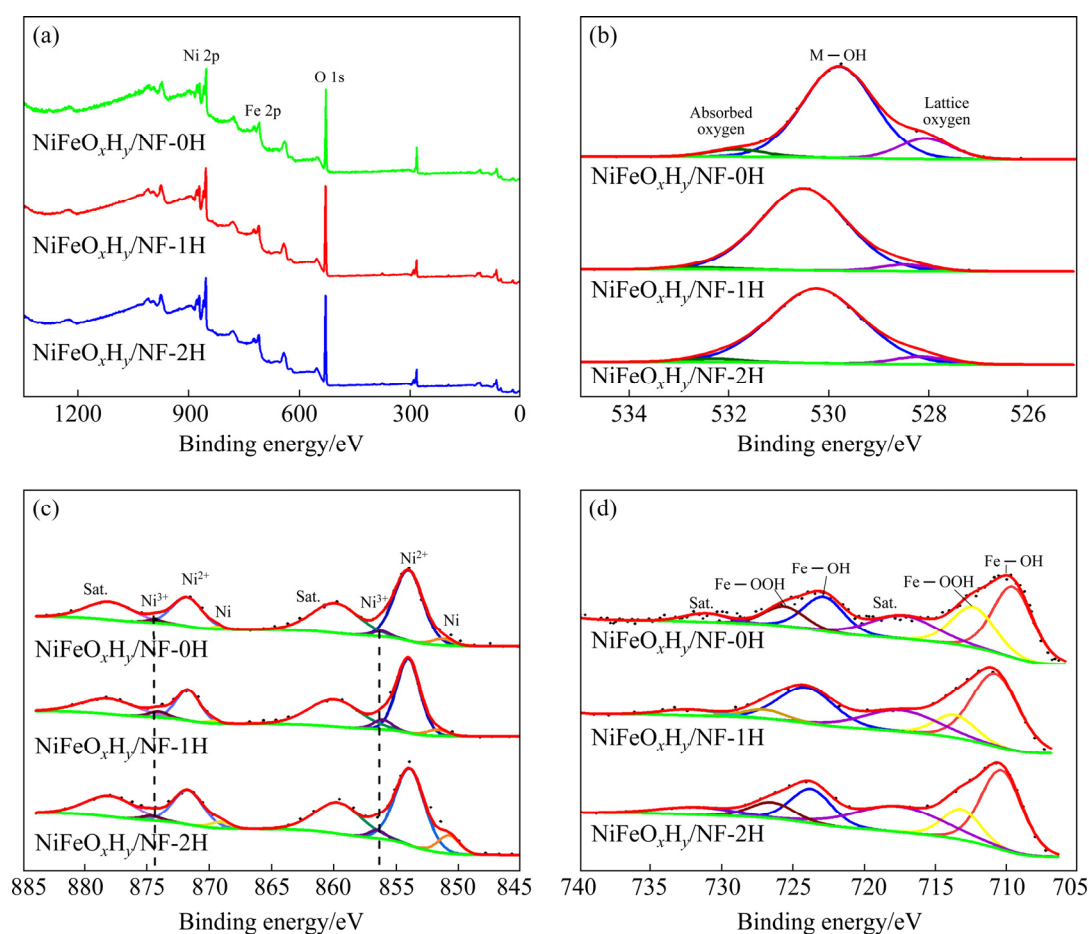

Fig. 4 XPS spectra of survey scan (a), O 1s (b), Ni 2p (c) and Fe 2p (d) of final catalysts of NiFeO$_x$H$_y$/NF-0H, NiFeO$_x$H$_y$/NF-1H and NiFeO$_x$H$_y$/NF-2H

3.2 Electrochemical properties of catalysts

The OER activities of the final catalysts of NiFeO$_x$H$_y$/NF-0H, NiFeO$_x$H$_y$/NF-1H, and NiFeO$_x$H$_y$/NF-2H were evaluated in 1 mol/L KOH by linear sweep voltammetry (LSV), as shown in Fig. 5(a). NiFeO$_x$H$_y$/NF-1H exhibited a much higher OER activity than NiFeO$_x$H$_y$/NF-0H and NiFeO$_x$H$_y$/NF-2H. It only requires an overpotential of 205 mV to generate current density of 50 mA/cm^2, which is much lower than those of NiFeO$_x$H$_y$/NF-0H (225 mV) and NiFeO$_x$H$_y$/NF-2H (243 mV). The fast OER catalytic kinetics of NiFeO$_x$H$_y$/NF-1H was further confirmed by the low Tafel slope of 30 mV/dec, compared to the other two samples (Fig. 5(b)). More importantly, NiFeO$_x$H$_y$/NF-1H can rank among the most active catalysts reported

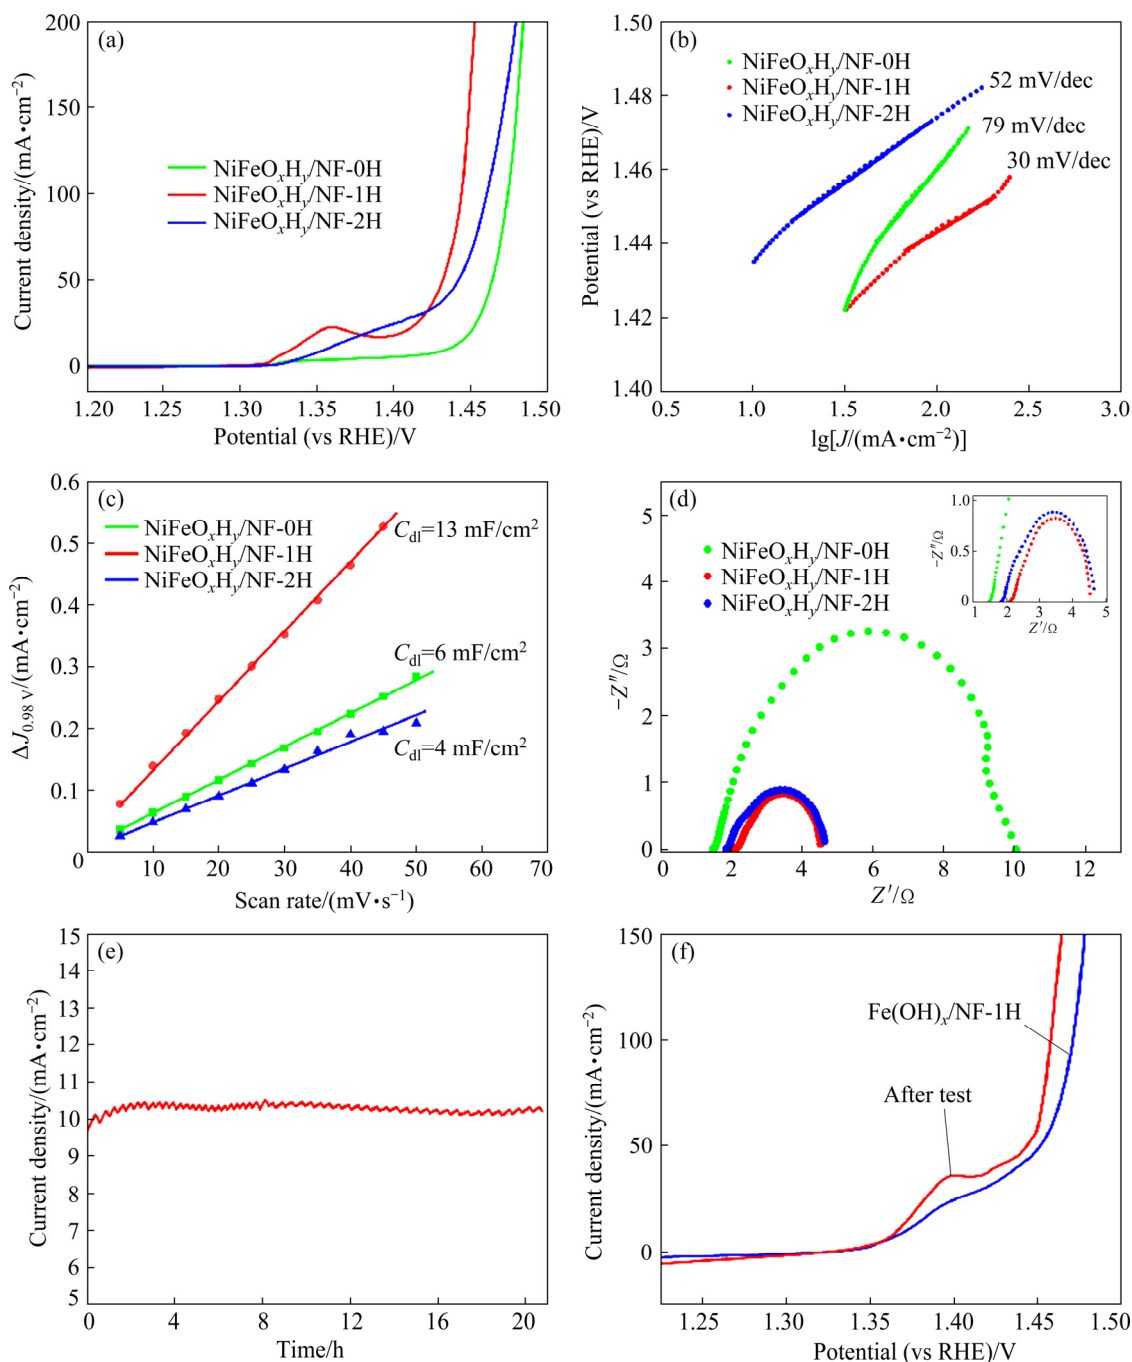

Fig. 5 LSV curves (a), Tafel plots (b), capacitive currents as function of scan rate (c) and Nyquist plots (overpotential=205 mV) (d) of final catalysts of NiFeO$_x$H$_y$/NF-0H, NiFeO$_x$H$_y$/NF-1H and NiFeO$_x$H$_y$/NF-2H, long-term stability test at 1.42 V (vs RHE) of NiFeO$_x$H$_y$/NF-1H (e), and LSV curves of NiFeO$_x$H$_y$/NF-1H before and after stability test (f)

recently. To explain the difference among activities, more electrochemical measurements were carried out. Activities are universally acknowledged to be closely related to surface area which is predicted to determine the double-layer capacitance (C_{dl}). As shown in Fig. 5(c), C_{dl} of the as-prepared catalysts is consistent with the OER activities, with an order of NiFeO$_x$H$_y$/NF-1H > NiFeO$_x$H$_y$/NF-0H > NiFeO$_x$H$_y$/NF-2H. The larger surface area of NiFeO$_x$H$_y$/NF-1H can be ascribed to the optimal structures of (oxy)hydroxide nanosheets, which can provide a tremendous amount of active sites. In addition, the presented electrochemical impedance spectroscopy (EIS) plots in Fig. 5(d) reveal a lower resistance of NiFeO$_x$H$_y$/NF-1H than those of the other two samples, due to the flower-like morphology with high conductivity of catalysts. The high OER activity of NiFeO$_x$H$_y$/NF-1H can therefore be attributed to its optimal nanosheets structures with a flower-like morphology, providing more active sites and high efficiency for the reaction and allowing the facial contact of solution, fast release of the produced gaseous molecules, and high conductivity. Additional measurement was carried out to confirm the formation of NiFe (oxy)hydroxide than pure Fe (oxy)hydroxide on the Ni foams. As shown in Fig. 6, the 1H catalysts on carbon cloths show much lower OER activity than that on Ni foams. This is because the 1H catalysts on carbon cloths are mainly composed of Fe-based (oxy)hydroxides with the low electrical conductivity. The present results suggest that the Fe phosphate under CV activation in alkaline condition can result in leaching of Ni from the NF, thus forming NiFe (oxy)hydroxides.
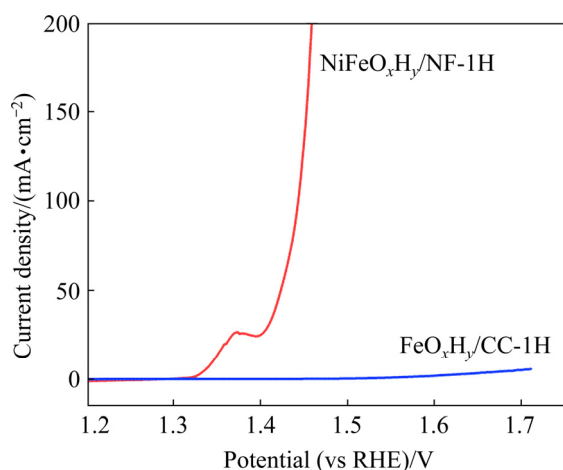

Aside from the activity, the stability of the catalysts is rather crucial for practical applications. Figure 5(e) shows $J−t$ curve at 1.42 V (vs RHE) of NiFeO$_x$H$_y$/NF-1H for 20 h with stable current density, indicating good stability. Moreover, LSV curves of NiFeO$_x$H$_y$/NF-1H before and after stability test only showed a small change (14 mV) of the overpotential at 50 mA/cm^2 (Fig. 5(f)), further confirming its good long-term stability. XPS and SEM were also conducted to verify the electronic state and morphology of the catalysts after stability test. As shown in Figs. 7(a) and (b), high-resolution XPS spectra of Fe 2p indicate the core doublet at 724.3 and 710.0 eV assigned to Fe^{3+}, while O 1s spectrum shows negligible changes with the strong peak at 530.2 eV, indicating that NiFeO$_x$H$_y$ was stable after stability test [40]. Moreover, the nanosheets structures of NiFeO$_x$H$_y$/NF-1H were largely retained after test (Fig. 7(c)), confirming its good stability.

3.3 Mechanism of diverse effects of precursors

Based on the current observations, it is demonstrated that the various precursors (Na$_3$PO$_4$, Na$_2$HPO$_4$ and NaH$_2$PO$_4$) have different effects on the structure, morphology, and thus the activity of the final catalysts. We tentatively attribute these to the pH dependent effects. Na$_3$PO$_4$ can provide a more alkaline environment (pH=12.5) with excessive OH$^−$, which may induce the slight formation of NiFeO$_x$H$_y$ on the surface before the reconstruction via CV cycles. This may then block the formation of layered NiFeO$_x$H$_y$ nanosheets during the reconstruction process. On the contrary, the slightly acidic condition provided by H$_2$PO$_4^−$ (pH=3.6) may also restrain the formation of layered NiFeO$_x$H$_y$ nanosheets during the CV cycles. To verify the pH dependent effect, a sample was synthesized with iron nitrate and KOH as precursors (pH=13.4), named as NiFeO$_x$H$_y$/NF-KOH. Similarly, the mixed precursor was dropped onto Ni foams and dried in vacuum as the precatalysts. Later, the final catalysts were obtained with 50 CV scans in 1 mol/L KOH. It is strongly aggregated as shown by the SEM image (Fig. 8). This can be ascribed to the certain amount of NiFeO$_x$H$_y$ formed during the mixing of iron nitrate and KOH, which then limits the formation of nanosheets and only results in a significant aggregation of NiFe (oxy)hydroxides during CV

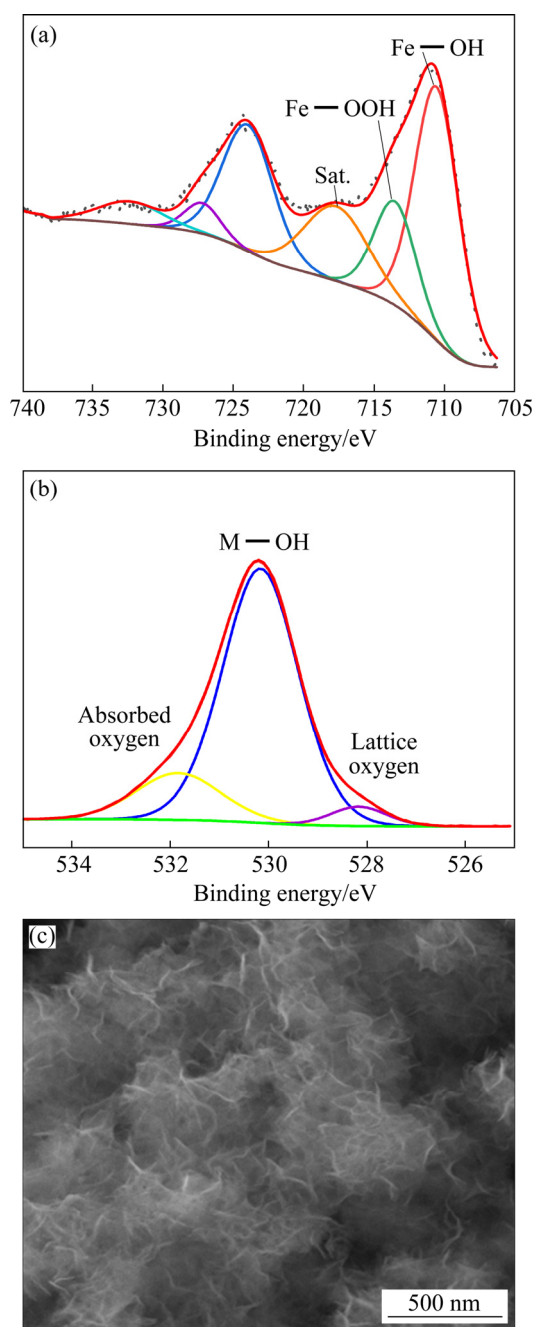

Fig. 6 Comparison of OER activity of 1H catalysts on Ni foam and carbon cloths

tested. Pure alcohol as solvent was avoided because ionization is unable to proceed without water. As shown in Fig. 9(a), the samples fabricated by pure water exhibit the poorest OER activity, because

Fig. 8 SEM image of $NiFeO_xH_y$/NF-KOH

Fig. 7 High-resolution XPS spectra of Fe 2p (a) and O 1s (b) of $NiFeO_xH_y$/NF-1H after stability test, and SEM image of $NiFeO_xH_y$/NF-1H after stability test (c)

scans. Therefore, a moderate pH value (9.8) induced by Na_2HPO_4 is critical for formation of nanosheets during the reconstruction process.

3.4 Effects of experiment conditions

Additional experiments were carried out to explore the effect of experimental conditions on the performance of the catalysts. To find the ideal solvent (water and alcohol) for the precursors, three different molar ratios of water to alcohol were

**Fig. 9** LSV curves of $NiFeO_xH_y$/NF-1H synthesized from precursors with molar ratio of water to alcohol=1:0 (pure water), 2:1 and 1:2 as solvent (a), and $NiFeO_xH_y$/NF-1H with different loading amounts of Fe^{3+} (0.015, 0.02, 0.025, and 0.03 mmol) on Ni foam (b) (The as-prepared $NiFeO_xH_y$/NF-1H in our work was obtained from precursors with molar ratio of water to alcohol= 2:1 and 0.025 mmol Fe^{3+})
Fig. 10 SEM images of NiFeO$_x$H$_y$/NF-1H synthesized from precursors with water to alcohol molar ratio of 1:0 (pure water): (a, d) 2:1; (b, e) 1:2; (c, f) As-solvent

alcohol can enhance the dispersion of precursors on Ni foam, which can effectively reduce the agglomeration thus provide more sites for the growth and formation of NiFeO$_x$H$_y$ nanosheets. This result can be demonstrated by SEM images of the precursors with different ratios of water to alcohol. As shown in Fig. 10, the precursors with pure water are agglomerated on Ni foam, while those with alcohol and water are uniformly distributed on Ni foam. Therefore, a proper ratio of solvent (2:1) can be beneficial to the growth of (oxy)hydroxide nanosheets, thus enhancing activities of the as-prepared catalysts. It is universally acknowledged that loading mass is unable to be overlooked while designing the catalysts. The increase of the amount of catalysts may significantly affect the performance of catalysts. The LSV curves in Fig. 9(b) reveal the enhanced performances with the increase of loading amount of Fe^{3+}, where excessive catalysts on Ni foam will only reduce the OER activity, probably due to the overgrowth of NiFe (oxy)hydroxides.

4 Conclusions

(1) A series of pre catalysts with different phosphate precursors on Ni foam were successfully synthesized via co-precipitation, which were transformed into NiFe (oxy)hydroxide during electrochemical activation in alkaline electrolytes.

(2) Different phosphate precursors have diverse effects on the morphology and performances of catalysts after electrochemical activation, due to different environments and morphologies caused by the precursors.

(3) The final catalysts with Na$_2$HPO$_4$ (NiFeO$_x$H$_y$/NF-1H) have a morphology of nanosheets to provide a tremendous amount of active sites, which thus displays outstanding electrochemical activity (an overpotential of 205 mV at 50 mA/cm^2), low Tafel plot (30 mV/dec) and high durability.

磷酸盐前驱体对泡沫镍上生长的
镍/铁羟基氢氧化物形貌及析氧反应性能的影响

摘　要：通过共沉积法和电化学激活法在泡沫镍网上生长制备镍/铁羟基氢氧化物纳米片。研究发现，不同磷酸盐前驱体(Na_3PO_4、Na_2HPO_4 和 NaH_2PO_4)对最终催化剂的形貌及析氧反应活性有不同的影响。使用 Na_2HPO_4 制备的镍/铁羟基氢氧氯化物纳米片在 1 mol/L KOH 溶液中电流密度达到 50 mA/cm² 时所需过电位为 205 mV，Tafel 斜率低至 30 mV/dec，并可以在后续稳定性测试中保持稳定 20 h。
关键词：镍/铁羟基氧化物；铁基磷酸盐；析氧反应；电化学激活
